

A positron emission tomography (PET) scan is an imaging test that shows how your body's tissues and organs are working. The test uses a small amount of a radioactive substance called a tracer. Depending on the reason for the test, the tracer may show how cells use sugar, how blood flows, or how some proteins or other substances attach to cells. PET scans can help find changes linked to diseases such as cancer or brain conditions such as Alzheimer's disease.

- What is the FNAC Test?
- The FNAC method is typically performed in an outpatient department for sampling masses, such as those observed in the neck, breast, and diseases like lymphoma, [tuberculosis](#), etc. It serves as the initial step in identifying the underlying cause of abnormal swellings. An aspiration cytology test is recommended when a lump is discovered in the breast or neck. This test is used to determine if the lump is cancerous. Additionally, it is employed in diagnosing thyroid disease, salivary gland disease, and lymph node disease.

FNAC Test: Uses & Results

What is a bone density test?

A bone density test is used to measure bone mineral content and density. It may be done using X-rays, dual-energy X-ray absorptiometry (DEXA or DXA), or a special CT scan that uses computer software to determine bone density of the hip or spine. For various reasons, the DEXA scan is considered the "gold standard" or most accurate test.

This measurement tells the healthcare provider whether there is decreased bone mass. This is a condition in which bones are more brittle and prone to break or fracture easily.

A bone density test is used mainly to diagnose osteopenia and [osteoporosis](#). It is also used to determine your future fracture risk. The testing procedure typically measures the bone density of the bones of the spine, lower arm, and hip. Portable testing may use the radius (1 of the 2 bones of the lower arm), wrist, fingers, or heel for testing, but is not as precise as the nonportable methods because only one bone site is tested.

Arthroscopy (ahr-THROS-kuh-pee) is a procedure that uses a fiber-optic camera to diagnose and treat joint problems. A surgeon inserts a narrow tube attached to a fiber-optic video camera through a small incision — about the size of a buttonhole. The view inside the joint is transmitted to a high-definition video monitor.

Arthroscopy allows the surgeon to see inside the joint without making a large incision. Surgeons can even repair some types of joint damage during arthroscopy, with pencil-thin surgical instruments inserted through additional small incisions

Biopsy

A biopsy is a procedure to remove a piece of tissue or a sample of cells from your body so that it can be tested in a laboratory. You may undergo a biopsy if you're experiencing certain signs and symptoms or if your health care provider has identified an area of concern. A biopsy can determine whether you have cancer or another condition.

Imaging tests, such as CT scans or MRIs, are helpful in detecting masses or irregular tissue, but they alone can't tell the difference between cancerous cells and cells that aren't cancerous. For most cancers, the only way to make a diagnosis is to perform a biopsy to collect cells for closer examination.

Needle biopsy

Needle biopsy is a general term that's often used to describe inserting a special needle through the skin to collect cells from a suspicious area. Doctors call this a percutaneous tissue biopsy.

A needle biopsy is often used on suspicious areas that your health care provider can feel through your skin, such as breast lumps and enlarged lymph nodes. When combined with an imaging procedure, needle biopsy can be used to collect cells from an area that can't be felt through the skin.

Endoscopic biopsy

During endoscopy, your health care provider uses a thin, flexible tube (endoscope) with a light on the end to see structures inside your body. Special tools are passed through the tube to take a small sample of tissue to be analyzed.

What type of endoscopic biopsy you undergo depends on where the suspicious area is located. The endoscope can be inserted through your mouth, rectum, urinary tract or a small incision in your skin.

Skin biopsy

A skin biopsy removes cells from the surface of your body. A skin biopsy is used most often to diagnose skin conditions, including melanoma and other cancers. The type of skin biopsy you undergo will depend on the type of cancer suspected and the extent of the suspicious cells.
